Add margining capability to a dc/dc converter

Brian Vasquez, Maxim Integrated Products, Dallas, TX

You can easily add margining capability—that is, the ability to digitally adjust the output voltage—to a dc/dc converter by making a single connection to the circuit (Figure 1). The dashed line in the figure shows the connection. The extra IC is a two- or four-channel, FC (inter-integrated-circuit)-adjustable-current DS4402 or DS4404 DAC. Because each DAC output is 0 mA at power-up, the extra circuitry is essentially transparent to the system until you write a command using the FC bus.

For example, assume that the input voltage is 3 to 5.5V; the output voltage is 1.8V, which is the desired nominal output voltage; and the feedback voltage is 0.6V. You can obtain the feedback voltage from the dc/dc converter’s data sheet; be sure to verify that it is within the output-voltage range that the current DAC’s data sheet specifies as sinking or sourcing voltage depending on whether you are sinking or sourcing current. You should also verify the input impedance of the dc/dc converter’s feedback pin. The circuit in Figure 1 assumes a high impedance.

Assume that you want to add a ±20% margining capability to the dc/dc converter’s output so that the maximum, nominal, and minimum output voltages would be 2.16, 1.8, and 1.44V, respectively. First, determine the necessary relationship between R_f and R_n, which yields the nominal output when the current of the DS4404 DAC is 0 mA:

\[
V_{FB} = V_{OUTNOM} \left( \frac{R_2}{R_2 + R_1} \right) \quad (1)
\]

where \( V_{FB} \) is the feedback voltage and \( V_{OUTNOM} \) is the nominal output voltage. Solving for \( R_1 \),

\[
R_1 = R_2 \left( \frac{V_{OUTNOM}}{V_{FB}} - 1 \right) \quad (2)
\]

For this example,

\[
R_1 = R_2 \left( \frac{1.8V}{0.6V} - 1 \right) = 2 \times R_2. \quad (3)
\]

Summing the currents at the feedback node derives the current to make the output voltage increase to the maximum output voltage:

\[
I_{R1} = I_{R2} + I_{DS4404}, \quad (4)
\]

where \( I_{R1} \) is the current through \( R_1 \), \( I_{R2} \) is the current through \( R_2 \), and \( I_{DS4404} \) is the current into the DAC.

\[
I_{DS4404} = I_{R1} - I_{R2}. \quad (5)
\]

\[
I_{R1} = \left( \frac{V_{OUTMAX} - V_{FB}}{R_1} \right) I_{R2} = \left( \frac{V_{FB}}{R_2} \right) \quad (6)
\]

where \( V_{OUTMAX} \) is the maximum output voltage.

\[
I_{DS4404} = \left( V_{OUTMAX} - V_{FB} \right) \left( \frac{V_{FB}}{R_1} \right) \quad (7)
\]

You can simplify Equation 7 by solving Equation 1 for \( R_1 \), and then substituting, which yields:

\[
I_{DS4404} = \frac{V_{OUTMAX} - V_{OUTNOM}}{R_1} \quad (8)
\]

In margin percentage, you can express Equation 8 as:
A better approach to designing an RTD interface with a spreadsheet

Aubrey Kagan, Emphatec, Markham, ON, Canada

An earlier Design Idea described how to linearize the output of an RTD (resistance-temperature-detector) sensor and how to calculate the resistor values using a spreadsheet (Reference 1). That idea limited the use of Microsoft (www.microsoft.com) Excel to calculating the coefficients you need for the polynomial expression and stopped short of using Excel to calculate the resistor values. You can generalize this proposed approach such that you can select any type of RTD and any temperature range, but this Design Idea limits the details to the following example.

You can download the worksheet (Figure 1) from the Web version of this Design Idea at www.edn.com/080918di1. You plot the chart as an XY diagram, and you create the trend line on the chart using a second-order polynomial, which will appear on the chart. The original Design Idea included this information. Unfortunately, you cannot access the coefficients you generate in this way from the worksheet, so you cannot directly calculate the resistor values.

To access the polynomial coefficients, you can use Excel’s LINEST
array formula. It prescribes a specific way of entering data; without that protocol, Excel will not provide the desired results. LINEST returns a number of regression statistics; to allow for these statistics, you must first highlight the range on the worksheet on which you want the regression results. Only the polynomial coefficients are important in this example, so this Design Idea limits the returned results by selecting block B24:D24 for those three values. You then enter the following line into the formula bar at the top of the worksheet: =LINEST(G5:G21,E5:F21,TRUE).

Simultaneously press the Control, Shift, and Enter keys rather than just Enter to terminate this command. The coefficients will then drop into the selected range. Excel will add the braces, {}, to indicate the array formula. The input range of the function in the formula above includes the $V_I$ column, allowing LINEST to create a second-order polynomial equation.

You can enter user-selected values as set numbers, providing easy and quick modification and an immediate update of the calculated values. These values include the current source through the RTD, the reference voltage, and the value of $R_7$ and $R_9$, all of which are “named” cells that the formulas refer to. The idea rewrites the original formulas to isolate the desired variable. You will find each in the associated cells for $R_6$, $R_8$, and $R_{10}$ on the worksheet. You could also complete the model by creating an automatic look-up of standard resistor values (Reference 2).

Shunt regulator monitors battery voltage

Vladimir Rentyuk, Modul-98 Ltd, Zaporozhye, Ukraine

A TL431 shunt regulator is a perfect choice for many applications. You can use it as a comparator with hysteresis by taking advantage of its inner voltage reference along with few additional components. You can use this comparator with hysteresis, like a Schmitt trigger, as a simple battery monitor (Figure 1). You calculate the threshold voltage, $V_{T+}$, of this comparator as $V_{T+} = V_{REF} \times (1 + R_3/R_2)$, where $V_{REF}$ the internal reference voltage of shunt-regulator TL431, is 2.5V.

When the battery voltage is higher than the threshold voltage, the cathode voltage of the TL431 is at its low level of approximately 2V, and transistor $Q_1$ turns on, lighting LED 1. You calculate the release voltage, $V_{T-}$, of the trigger as $V_{T-} = V_{REF} \times (1 + R_2/(R_1 + R_3) \times 1/R_2)$.

When the battery voltage is less than the release voltage, the cathode voltage of the TL431 goes to its high level—to the battery voltage. Transistor $Q_1$ turns off, and LED 1 does not shine. LED 2 turns on again when the battery voltage, after recharging, exceeds the threshold voltage.
Power supply meets automotive-transient-voltage specs

Francesc Casanellas, Aiguafreda, Spain

Figure 1 shows a power supply that delivers 5V from a 12V battery. With only a few components, the supply copes with all the automotive transients that ISO (International Organization for Standardization) 7637-1 lists without the need for a bulky transient-voltage suppressor. In normal operation, $R_3$ connects to the common through a microcontroller port. In standby mode, $R_1$ stays open, and the quiescent current of the supply decreases from approximately 2.8 mA to approximately 160 $\mu$A, and the output voltage then drops to approximately 3.5V. If your application doesn’t require a standby mode, suppress $R_3$ and set $R_1$ to 120$\Omega$ and $D_1$ to 4.3V. You can use the circuit in 24V systems if $D_2$ is 36V. If the voltage increases, the current through $D_2$ and the base of $Q_2$ increases, so $Q_2$ increases the current of $Q_1$, which lowers the gate-to-source voltage of $Q_1$. If the input voltage surpasses 19V, $D_2$ starts to conduct and makes $Q_2$ switch off $Q_1$, so permanent overvoltages as high as 200V cannot damage the circuit. The Miller capacitance of $Q_1$ makes it act as a fast integrator, which keeps the system stable. If you remove $D_2$, you must replace $Q_1$ with a high-voltage transistor, such as an MMBTA42.

If you omit $D_2$, the circuit cannot withstand permanent overvoltages without $Q_1$’s overheating. In this case, however, the circuit can cope with all the impulses, including the load-dump pulse, of ISO 7637-1. You should remove $D_2$ only if $C_1$ cannot maintain the voltage during long overvoltages, such as the load-dump pulse, and keeping the voltage is critical.

An added advantage of this circuit over most IC-voltage regulators is that it can sink current through $D_1$ and $Q_1$. This feature allows the use of diodes to fully protect the microprocessor’s inputs. Soldering the D-Pack package to a couple of 1-cm$^2$ copper pads allows the circuit to source 300 mA at 10 to 16V or 150 mA at 20 to 32V. More dissipation area allows for higher currents.

Locked-sync sine generator covers three decades with low distortion

Alfredo H Saab and Tina Alikahi, Maxim Integrated Products, Sunnyvale, CA

Analog applications, such as testing, calibration, and general system operation, often require a sine waveform of accurate amplitude and frequency, with low THD (total harmonic distortion). Some applications demand that the generator of such waveforms have the ability to accurately synchronize the output with an external timing signal. Simple sine-wave generators can offer various degrees of this performance, but maintaining low THD with constant amplitude is a problem, particularly if the output and the synchronization signal must remain locked through an extended range of frequencies.

The circuit in Figure 1 can synchronize a sine-wave output through three decades of frequency—20 Hz to 20 kHz—and maintain low THD and constant amplitude (Table 1). The synchronizer IC, an NXP Semiconductors (www.nxp.com) 74HC4046, is a PLL (phase-locked loop) with a VCO (voltage-controlled oscillator) and a phase/frequency detector. It has three internal phase detectors, but this design uses the one with a frequency-capture range equal to that of the VCO-frequency range (the maximum frequency minus the minimum frequency).

The circuit’s general-purpose binary frequency divider, the 74HC4060, connects between the VCO output and the 74HC4046 feedback (phase/frequency-comparator) input and has a division ratio of 64. When the PLL is locked, therefore, the Q6 output of the 74HC4060 generates a square wave equal to 1/64th of the VCO-output frequency. The components
that determine the 74HC4046 center frequency, C₁ and R₁, determine the VCO-frequency range from 20×64 to 20,000×64 from the minimum to the maximum level of the VCO’s input-voltage range.

A switched-capacitor lowpass filter, the Maxim (www.maxim-ic.com) MAX297, whose cut-off frequency by design equals 1/50th of the clock frequency you apply to it, has for signal input the same square wave it uses for the PLL feedback, and its clock input attaches to the VCO output. Because the clock and signal inputs always have a frequency ratio of 64, the input signal always falls within the filter bandpass. No input harmonics fall within this bandpass because the ratio of the clock frequency to frequency is less than 50 for all of them. (For the lowest second harmonic, the ratio is 32.) The THD, up to the 32nd harmonic, is lower than 0.1%.

The fact that the filter’s input signal is a square wave with a 50% duty cycle helps in this application because a square wave contains only odd harmonics of the fundamental, and the lowest-frequency harmonic is the third, which is well within the filter’s deep-attenuation range.

You can frequency-modulate the synchronization signal, but that task entails a compromise between the synchronization-tracking speed (or maximum modulation frequency and depth) and the frequency-locking range, which the PLL’s lowpass filter components, R₂, R₃, and C₂, set. Modulation speed is limited for the values the figure shows because those values are optimized for an extended-frequency locking range. You can download more information, including a full data sheet for the MAX297, from www.maxim-ic.com (Reference 1).
